

METHOD AND APPARATUS FOR DISPLAYING IMAGES

BACKGROUND OF THE INVENTION

FIELD OF THE INVENTION

The present invention relates to a method and apparatus for displaying images. More particularly, the present invention relates to a method and apparatus for displaying images based upon the brain's ability to perform binocular summation of differing images.

RELATED ART

Head-mounted display systems for displaying images to a user's eyes or eye are known. Conventional head-mounted display systems typically include a head-mounted portion, the head-mounted portion having image-generating devices for generating images viewable by the user. Head-mounted display systems are typically used to convey computer generated information, data from sensing devices, or programmed entertainment such as moving or still images, which are often accompanied by audio signals for reception by a user's ears. One such conventional head-mounted display system 10 is illustrated by Figs. 1 and 2.

The conventional head-mounted display system 10 includes a head-mounted portion 12, which includes right and left image displays 16, 18 and right and left eyepiece optics 20, 22, for displaying images to a user's eyes 21, 23. A controller 25 conveys image signals to the head-mounted portion 12 via a cable 14, which right and left lines 24, 26 for conveying image signals to the right and left image displays 16, 18, respectively.

1 The controller 25 is comprised of an image source 30, which transmits image data to a
2 processor 28, which is then formatted for transmission to the right and left image displays
3 16, 18 via the lines 24, 26.

4 In the conventional head-mounted display system 10, the right and left image
5 displays 16, 18 each display identical images to the right eye 21 and to the left eye 23 of a
6 user – which is known as the “biocular” mode of displaying images. Fig. 3 illustrates a
7 simplified example of the images displayed to the right eye 21 and the left eye 23 of a user
8 of the conventional head-mounted display system 10. Because the images displayed to the
9 right eye 21 and to the left eye 23 of the user are identical, the user's brain does not gain
10 additional information from the use of two image displays above what could be obtained
11 from the use of one image display. The information contained in the image displayed to
12 one eye is therefore redundant to the image displayed to the other eye.

13 Because each of the user's eyes are presented identical images, both the right and
14 the left image displays 16, 18 must be of relatively high resolution (i.e., having a high
15 number of individual pixels per unit area) in order to display an image having a desired
16 sharpness. Specifically, if an image of $n \times m$ resolution (i.e., an image formed from an $n \times$
17 m array of pixels) is desired to be perceived by the user's brain, each of the right and left
18 image displays must include at least an $n \times m$ array of pixels. This is undesirable because
19 the cost of image displays increases with increasing resolution. In addition, high
20 resolution display signals require higher storage and processing capabilities, which further
21 adds to the cost of the head-mounted display system 10.

22 An alternative conventional head-mounted display is disclosed in U.S. Patent No.
23 5,726,670 to Tabata et al. Tabata discloses increasing the resolution of selected portions
24 of a display by using multiple display apparatuses to convey overlapping images. As

1 illustrated by figure 1 of Tabata, separate images (b) and (c) are combined via differing
2 optical paths to form an image (d). While the desired degree of resolution is obtained in
3 image (b), Tabata's apparatus requires multiple optical systems to convey the overlapping
4 images.

Therefore, a need exists for a method of displaying images that provides an image of desired resolution, and that is not unduly expensive. A need also exists for an apparatus for displaying images of desired resolution that is not unduly expensive.

SUMMARY OF THE INVENTION

10 The present invention overcomes the shortcomings of the conventional art and may
11 achieve other advantages not contemplated by the conventional art.

12 According to a first aspect of the invention, a method and an apparatus for
13 displaying images are addressed to displaying images using two displays, each display
14 being arranged to present an image to an eye of a user. A right image is displayed on a
15 right display, the right image being generated from a first portion of a source image signal,
16 and a left image is displayed on a left display, the left image being generated from a
17 second portion of the source image signal. The second portion of the source image signal
18 differs from the first portion of the source image signal, allowing the user's brain to
19 perform binocular summation of the information contained in the right and left images to
20 form a perceived, composite image.

According to the first aspect of the invention, each eye is presented a different image, and therefore more information from the source image signal is communicated to the user's brain than would be if both displays displayed the same image. Because the

1 human brain can extract details from and sum the different images, the composite image
2 has a higher perceived resolution than each of the individual right and left images.

3 Other aspects and advantages of embodiments of the invention will be discussed
4 with reference to the figures and to the detailed description of preferred embodiments.

Fig. 9 illustrates a hypothetical source image as displayed by a 2p x 2q display.

23

Fig. 10 illustrates a symbolic representation of a composite image perceived by a

24

user according to an embodiment of the present invention.

1 is arranged to receive a source image signal from an image source 58. The controller 50
2 includes a processor 54, a sampler 56, and an analog-to-digital converter (ADC) 57.

3 Fig. 5 is a schematic diagram illustrating the processor 54. The processor 54
4 comprises an address calculator 53 disposed to receive image signal data from the sampler
5 56, and a right frame buffer 55 and a left frame buffer 59 for receiving formatted image
6 data from the address calculator 53.

7 The elements comprising the controller 50 and the processor 54 are all illustrated
8 as individual elements for the purposes of illustration. However, one or more of these
9 elements can comprise routines or instructions stored on and executable by, for example, a
10 processing unit or units, software and other computer readable media used in conjunction
11 with a computing device, and other devices capable of executing stored instructions.

12 The image display device 40 may also have audio capability, and an audio signal
13 source 60 can be included to provide source audio signals to the controller 50. Speakers
14 62, 64 may be arranged to receive audio signals from the controller 50 and to produce
15 audio output from the audio signals. The audio output produced by the speakers 62, 64 can
16 be correlated with the images displayed by the displays 42, 44 in order to create, for
17 example, a desired entertainment program for the user.

18 The right and left displays 42, 44 can comprise any displays capable of displaying,
19 in general, a $p \times q$ array of individual, discrete portions of an image (e.g., a $p \times q$ array of
20 "pixels"). In the context of head-mounted displays, displays are commonly referred to as
21 "microdisplays." Examples of microdisplays suitable for use in the present invention
22 include liquid crystal displays (LCDs), light emitting displays (LEDs), electro-luminance
23 (EL) displays, electro-chromic (EC) displays, and other displays capable of displaying
24 individual pixels. Further, small scanning display devices using CRTs, and laser diodes

1 used to create small displays, or to write directly on the retina, may also be used.
 2 According to an aspect of the invention, the image display device 40 is capable of
 3 displaying an image of a high perceived resolution (specifically, as perceived by the user's
 4 brain) to a user by taking advantage of the brain's ability to perform binocular summation
 5 of two different images, one image being presented to the user's left eye 47, and one image
 6 being presented to the user's right eye 45. "Binocular summation" refers to the brain's
 7 ability to combine two images into a single image that appears to be sharper than the
 8 individual images.

9 The two differing images are displayed to the right and left eyes 45, 47 using the
 10 right and left displays 42, 44, respectively. In general terms, the two differing images are
 11 produced when the processor 54 transmits a display signal to the right display 42 that is
 12 generated from only a portion of the data sampled from the source image signal, and,
 13 when the processor 54 transmits a display signal to the left display 44 that is generated
 14 from another portion of the data sampled from the source image signal. When the
 15 differing images displayed by the right and left displays 42, 44 are received by the right
 16 eye 45 and the left eye 47 of the user, respectively, the user's brain performs binocular
 17 summation of the differing images, and a composite image is perceived by the user's brain.

18 In the above embodiment, because the images displayed by the right and left
 19 displays 42, 44 differ, more information is conveyed to the user's brain than would be
 20 conveyed if identical images were presented to each of the user's eyes 45, 47. Therefore,
 21 in some cases, twice as much information may be conveyed to a user's brain than would be
 22 conveyed if the same image were displayed by both the right and the left displays 42, 44.
 23 The composite image as perceived by the brain therefore has a perceived resolution which
 24 is greater than that which could be conveyed by displays having the same number of pixels

1 (p x q) using a display technique in which the same image is presented to each of the eyes
2 45, 47.

3 The operation of the image display device 40 will now be discussed with reference
4 to Fig. 6.

5 In step S10, the image source 58 transmits a source image signal to the sampler 56.
6 The image source 58 can be, for example, a storage device capable of storing or buffering
7 image data from an image generating source, a camera device for receiving actual images
8 and reducing the images to electronic form, or, a combination of the two devices. The
9 image source 58 can also include a digital storage system such as an optical disk or a
10 magnetic storage disk. Alternatively, the image source 58 could include a magnetic
11 storage tape. The term "source image signal" is used in this specification to indicate, for
12 example, a digital or an analog signal containing data capable of describing a single frame
13 of an image, a series of frames of images, or both. If the source image signal is an analog
14 signal, it can be digitized at the ADC 57 before sampling. Alternatively, the source image
15 signal could be processed in the controller 50 in the analog domain, and digitization would
16 be unnecessary. If the source image signal provided by the image source 58 is in digital
17 format, it can be forwarded directly to the sampler 56.

18 The sampler 56 samples the source image signal in step S12, and transmits the
19 image signal data to the processor 54. In step S14, the processor 54 divides the image
20 signal data from the sampler 56 into a first and second portion of image data values. In
21 step S16, the processor 54 uses the first and second portions of image data values to
22 generate right and left display signals for display by the right and left displays 42, 44. The
23 right and left display signals are transmitted to the right and left displays 42, 44,

1 respectively, in step S18, and the right and left displays 42, 44 display right and left
2 images in step S20.

3 For the purposes of this discussion, the right and left displays 42, 44 are described
4 as having p rows and q columns, forming $p \times q$ arrays of pixels. Figs. 8A and 8B illustrate
5 a simplified depiction of images displayed by the left display 44 and the right display 42,
6 respectively.

7 In order to effectuate binocular summation, the sampler 56 samples the source
8 image signal at a rate such that the image signal data includes a sufficient number of
9 image data values so that differing display signals can be provided to the right $p \times q$
10 display 42 and to the left $p \times q$ display 44. Each image data value sampled from the
11 source image signal includes information regarding the brightness and color of a particular
12 pixel. In a preferred embodiment, the sampler 56 samples at a rate sufficient to generate a
13 number of image data values to display an image of $2p \times 2q$ resolution. Fig. 9 illustrates
14 how a displayed image would appear if all of the sampled data were used to display an
15 image on a $2p \times 2q$ display.

16 According to an aspect of the present invention, the processor 54 divides the
17 sampled image signal data into a first portion, including a right set of image data values,
18 which is used for generating display signals for the right display 42 (Fig. 8B), and, a
19 second portion, including a left set of image data values, which is used for generating
20 display signals for the left display 44 (Fig. 8A). The composite image formed by
21 binocular summation of the images of Figs. 8A and 8B is illustrated symbolically by Fig.
22 10.

23 The source image signal preferably contains data capable of describing a series of
24 frames of source images, and the data describing each frame can be sampled individually,

1 with the first and second portions of the image signal data each describing a part of a
2 frame.

3 According to the above embodiment, the right and left displays 42, 44 can have a
4 relatively low resolution, with the user perceiving a composite image of higher resolution.
5 Alternatively, displays of conventional resolution can be used in the image display device
6 40, and the sampler 56 can sample at a higher rate in order to provide differing display
7 signals to the respective displays. In this way, a composite image of increased perceived
8 resolution can be achieved using displays of conventional resolution.

9 The processor 54 can divide image signal data from the sampler 56 in several
10 ways, examples of which are discussed below. While the embodiments are discussed in
11 terms of a "source image signal," this term is not intended to limit the present invention to
12 the display of static images. Rather, a source image signal can include image data
13 communicating a series of frames of images, which can be converted, frame by frame, into
14 a series of display images for display on the right and left displays 42, 44.

15 A first embodiment of a method of dividing image signal data and generating
16 display signals is illustrated by Figs. 7, 8A, 8B, 9 and 10. Fig. 7 is a flow chart illustrating
17 the operation of the processor 54 in dividing image signal data and generating the right
18 and left display signals. Figs. 8A and 8B illustrate, respectively, the images to be
19 displayed by the right and left displays 42, 44. Fig. 9 illustrates a hypothetical $2p \times 2q$
20 array source image, which is used to demonstrate how the right and left sets of image data
21 values are selected. The hypothetical source image of Fig. 9 may represent, for example, a
22 frame from image data communicated by a source image signal. In the first embodiment,
23 data from the source image signal is sampled so as to select data from alternating columns
24 and rows of the source image.

1 A third embodiment of a method of dividing the image signal data is illustrated by
2 Figs. 13, 14A and 14B. Fig. 13 illustrates a hypothetical $2w \times 2z$ array source image for
3 illustrating how the respective sampled image signal data values are selected for display
4 on right and left displays of $2w \times z$ resolution.

5 According to the third embodiment of the method of dividing the image signal
6 data, the displays used to display the images of Fig. 14A and Fig. 14B have the same
7 vertical resolution as the hypothetical source image of Fig. 13, and half the horizontal
8 resolution of the hypothetical source image. In filling the image of Fig. 14A, the
9 controller uses the image data value sampled from column 1, row 1 to fill those same
10 columns in the left display, and fills column 1, row 3 of the display with the corresponding
11 value from Fig. 13. The right display is similarly filled.

12 According to the third embodiment, the user's brain performs binocular summation
13 of the "overlapping" columns from Figs. 14A and 14B, to arrive at an approximation of
14 the image of Fig. 13. A composite image approximating $2w \times 2z$ resolution can therefore
15 be achieved using displays of $2w \times z$ resolution.

16 The methods of dividing image signal data discussed above are intended to be
17 illustrative, and not exhaustive, of the possible methods of using binocular summation in
18 creating composite images. Other techniques, such as random sampling of the source
19 image signal and assigning random image data values for use in the right and left displays
20 42, 44, are also within the scope of the invention. Similarly, a single method for dividing
21 the image signal data need not be used across the entire array of the right and left displays
22 42, 44, and combinations of methods of dividing the image signal data can be used to
23 produced desired levels of resolution in specific areas of the composite image. In
24 addition, the portions of the image signal data used to generate the display signals for the

1 right and left displays 42, 44 need not be completely different, and image data values can
2 be shared among the two portions.

3 In the above embodiments, the image display device performs sampling, and in
4 some instances, analog-to-digital conversion of source image signals from the image
5 source 58. These steps may not be necessary if the image source 58 provides a source
6 image signal that already contains image data suitable for use by the processor 54. In that
7 case, the processor 54 can simply divide the image data from the source image signal into
8 the first and second portions necessary for generating the display signals for display by the
9 right and left displays 42, 44. Further, while the sampling rates are discussed as being
10 adequate to produce display signals for the right and left displays 42, 44, higher sampling
11 rates can be employed.

12 In the embodiment illustrated by Fig. 4, the elements comprising the image display
13 device 40 are shown as forming a single device 40 for the purpose of illustration, and the
14 relationship of the elements is not intended to be limitative of the present invention. For
15 example, Fig. 15 illustrates an alternative embodiment of an image display device having
16 modular components.

17 In the embodiment illustrated by Fig. 15, an image display device 65 comprises a
18 visor component 70, which is adapted to fit over a user's head, connected to a control unit
19 80 by a cable 82. The visor component 70 can include, for example, right and left
20 displays, right and left imaging lenses, and speakers. The control unit 80 can comprise a
21 controller for providing display signals to the displays, and additional features such as, for
22 example, functional displays, volume controls, on/off controls, and other controls. An
23 image/audio source 90 can include an audio signal source and an image source, the source
24 image signals and source audio signals being provided to the control unit 80 via a cable
